‘Bobo-Newton syndrome’: An unwanted gift from man’s best friend

Kristin Y Popiel MD1, Donald C Vinh MD2

**Capnocytophaga canimorsus** is a facultative Gram-negative bacillus that is typically a constituent of the oral flora of dogs and cats. It was first isolated by Bobo and Newton in 1976 from a man presenting with meningitis following a dog bite. Transmission to humans follows various animal-related injuries, which may be gross or subtle. *C canimorsus* can cause a spectrum of syndromes ranging from skin and soft tissue infection to invasive disease such as meningitis or endocarditis. The present article reports a case of *C canimorsus* meningitis in a patient with the classic risk factor of alcoholic liver cirrhosis. Clinical suspicion was confirmed by culture and genetic identification of the blood isolate. The present article reviews the **Capnocytophaga** genus, the clinical syndromes most commonly associated with this zoonotic organism, its laboratory identification and treatment.

**Key Words:** *Capnocytophaga canimorsus*; Dog bite; Gram-negative bacillus; Meningitis

In 1976, Bobo and Newton (1) described a syndrome that would forever change mankind's relationships with their canines. A previously undescribed, fastidious Gram-negative bacillus was isolated from blood and cerebrospinal fluid of a man who developed septicemia and meningitis approximately one week after a dog bite. In fact, these organisms had been referred to the Centers for Disease Control and Prevention (Georgia, USA) for identification since 1961, forming the 'dysgonic fermenter type 2' (DF-2) collection (2).

Shortly thereafter, Butler et al (3) reviewed the clinical and epidemiological findings for 17 patients from whose blood DF-2 strains were isolated, demonstrating that this organism was, in fact, the cause of the syndrome described by Bobo and Newton, and confirming the precipitating contact with dogs. Given that dogs are the most common household pets in North America and that approximately one million dog bites occur annually (4), the present report presents a case of *C canimorsus* meningitis in a patient with the classic risk factor of alcoholic liver cirrhosis. Clinical suspicion was confirmed by culture and genetic identification of the blood isolate. The present article reviews the **Capnocytophaga** genus, the clinical syndromes most commonly associated with this zoonotic organism, its laboratory identification and treatment.

**Case Presentation**

A 56-year-old man initially presented to a peripheral hospital with a four-day history of fever, headache and arthralgias, with nausea and retching. His medical history was significant for mixed connective tissue disease with associated Raynaud's phenomenon, which had caused several previous episodes of patchy, self-limited digital necrosis; he was never treated with immunosuppressants. He was also hypertensive and had benign prostatic hypertrophy. A few years previously, he was found to have a progressive mild thrombocytopenia (100×10^9/L) associated with mild hepatosplenomegaly; however, he was not compliant with further investigations. He regularly consumed alcohol, estimated by his wife to be six beers per day.

Soon after arrival to the hospital, the patient developed progressive obtundation requiring intubation. In the context of an altered mental status and concurrent fever, a meningitic and/or encephalitic process was suspected. A computed tomography scan of the head revealed no mass lesion or hemorrhage. Ampicillin, ceftriaxone, vancomycin and acyclovir were initiated before lumbar puncture. Dexamethasone was not administered. Cerebrospinal fluid was turbid, with 855 leukocytes/mL (97% neutrophils), 210 red blood cells/mL, elevated protein (2.7 g/dL) and low glucose (0.2 mmol/L); concomitant blood glucose was 7.04 mmol/L. No organisms were observed on Gram stain.

Because of profound neurological impairment, the patient was transferred to a tertiary care hospital. Within approximately 24 h, blood cultures from the initial hospital revealed a Gram-negative filamentous bacillus, also isolated from two sets of blood cultures at the referral centre. On careful examination, a small eschar at the base of the left index finger was noted (Figure 1). According to the patient’s wife and daughter, the recently acquired family dog had bitten the patient one week previously.

The constellation of a Gram-negative bacillary meningitis in an individual with probable cirrhosis and a dog-bite injury raised suspicion for **Capnocytophaga** meningitis. Other than thrombocytopenia, there was no evidence of disseminated intravascular coagulation (DIC). Antibiotics were eventually de-escalated to meropenem at a dose of 2 g every 8 h, pending speciation of the Gram-negative bacillus.

Despite significant disease revealed by magnetic resonance imaging of the brain, which demonstrated fluid levels in both ventricles, which demonstrated fluid levels in both ventricles, he recovered well and was discharged from the hospital three weeks later.
The genus *Capnocytophaga*, proposed by Leadbetter et al (5) in 1979, includes capnophilic, facultatively anaerobic, non-spore-forming Gram-negative bacteria of the family Flavobacteriaceae. The genus is infamous for two species, *C. canimorsus* (previously termed Centers for Disease Control and Prevention DF-2) and *Capnocytophaga cynodegmi* (DF-2-like). Their previous designation, ‘dysgonic fermenter’, referred to the phenotypic characteristics (ie, slow and relatively poorly fermenting bacterium, fermenting carbohydrates); their current species to the phenotypic characteristics (ie, slow and relatively poorly fermenting bacterium, fermenting carbohydrates); their current species to the genus using 16S ribosomal RNA gene sequencing, which confirmed the isolate to be *C. canimorsus* seven days after the blood cultures were drawn.

Microbiological identification of the Gram-negative bacillus was hampered by its fastidious nature. Although the organism was detected using BACTEC blood culture bottles (Becton Dickinson, USA) after approximately two days, primary subculture onto solid media revealed only poor growth in anaerobically incubated blood agar plates. Subculture onto chocolate agar incubated in CO₂ permitted sufficient growth for subsequent identification by the provincial reference laboratory (Laboratoire de Santé Publique du Québec, Sainte-Anne-de-Bellevue, Québec) via 16S ribosomal RNA gene sequencing, which confirmed the isolate to be *C. canimorsus* seven days after the blood cultures were drawn.

**DISCUSSION**

The genus *Capnocytophaga* is classified in the family Flavobacteriaceae, and the genus itself is divided into two species, *C. canimorsus* and *C. cynodegmi*. These species are commonly found in the oral flora of humans, constituting the previous DF-1 group, which can be found in the oral flora of these animals; using bacterial isolation methods, it has been detected in 25.5% of dogs and 21% of cats (8), and in 74% of dogs and 57% of cats using polymerase chain reaction sequencing methods (9). While this implicates domesticated canines and felines as the most likely source of human infections, illustrating the crucial need to obtain a history of animal exposures when evaluating patients, it should be noted that no clear documented animal source is identified in approximately 10% of cases (10).

The number of cases of human infections due to *C. canimorsus* was estimated to be 0.5 to 0.7 per one million inhabitants per year in large studies performed in Denmark and the Netherlands (11,12). This rate likely varies with different social, cultural and economic habits. These estimates are also skewed on the one hand by the frequent use of empirical antibiotics in the clinical management of animal bites and, on the other, by the fastidiousness of the organism and, thus, challenges regarding its isolation and identification in routine microbiology laboratories. Historically, infections due to *C. canimorsus* more commonly affect men (male:female ratio ranging from 2.7:1 to 3.75:1), with the mean age varying between 50 and 60 years of age (10,12-14), likely reflecting both the demographics of exposure and, importantly, the corresponding underlying risk factors. Since its first description, *C. canimorsus* infection (typically from splenectomy) and alcohol-induced liver disease have emerged as significant risk factors for severe, noncellulitis *C. canimorsus* infection (ie, septicemia, meningitis) (1,3,10,13,15,16). Although hematological malignancy and steroid use are often cited as risk factors for *Capnocytophaga* species infections, these predisposing conditions are, in reality, more commonly observed with invasive infections with species endogenous to humans, rather than the zoonotic ones. Of note, up to 40% of severe *C. canimorsus* infections have occurred in subjects in whom no underlying predisposing condition is apparent (13). Although complicated septicemia (eg, with DIC, organ failure and/or shock) tends to be more often reported in individuals with hypoplasmen or alcoholic liver disease, there are cases in which neither of these conditions is present. In such cases, *C. canimorsus* septicemia may reflect a sentinel manifestation of an acquired or congenital defect in host defenses.

Overall mortality rates for severe *C. canimorsus* infections range from 13% to 33% (11,12,17); notably, and perhaps paradoxically, meningitis portends a lower mortality rate of 5% (13).

**Laboratory identification**

*Capnocytophaga* species appear as long, slender Gram-negative bacilli with tapered ends, typically measuring 3 µm to 6 µm in length (18),
compared with 2 μm for Escherichia coli. Capnocytophaga species are slow-growing on solid media. Some isolates will grow better anaerobically on primary isolation, as in the present case but, typically, these bacteria are characterized by their requirement for 5% to 10% CO₂ enrichment for optimum growth. This capnophily is particularly apparent on attempts at subculture. The organisms grow best at 35°C to 37°C on either blood or chocolate agar. The type of ‘blood agar’ appears to be important; heart infusion agar with 5% rabbit blood allows colonies to appear within 24 h to 72 h, whereas Trypticase soy agar base with 5% sheep blood yields poorer growth (2,10,16). The addition of a Staphylococcus aureus streak to the agar plate has been reported to enhance growth of the organism, a phenomenon not reproduced by the use of ‘X’ (hemin) and ‘V’ (nicotinamide adenine dinucleotide) paper strips (19,20); this manoeuvre was not attempted in the present case. Capnocytophaga species do not grow on MacConkey agar. Visible colonies typically require two to four days of incubation to appear and are nonhemolytic. Colonial morphology is usually flat and irregular with fingerprint-like projections. These fingerprint-like projections are attributed to ‘gliding motility’ characteristic of this genus. The zoonotic Capnocytophaga species (C canimorsus, C cynodegi) are oxidase positive and catalase positive, whereas those constituting the human oral flora are oxidase negative and catalase negative.

16S ribosomal RNA gene sequencing has become the gold standard for the identification of bacteria with ambiguous biochemical profiles (21). This method has proved successful in distinguishing isolates from Capnocytophaga species (22), and has been widely reported in the literature as a specific and reliable diagnostic tool for C canimorsus (23-25).

Clinical syndromes
The incubation period between the microbial exposure from contact with an infected animal to development of symptoms is, on average, seven days (range one to eight days, occasionally up to 30 days) (13,26).

The zoonotic Capnocytophaga species infections result in various presentations. The most common is localized skin and soft tissue infection. Typically, patients present within hours after a dog bite; at this point, there may be little significant evidence of local inflammation. Later, infection may present with localized cellulitis, pain at the site of injury, a purulent discharge, lymphangitis and regional lymphadenopathy. However, these rarely progress to more severe disease because they occur within the context of obvious bite injuries, which are typically treated preventively with antibiotics.

On the other hand, more dramatic presentations include fulminating septicemia, peripheral gangrene or meningitis, which are not uncommonly reported in the literature. Unlike their skin and soft tissue infection counterparts, these severe manifestations are not preceded by gross injury, but often by apparently benign bites, scratches or even licks. In our case, the history of the dog bite was suggested by the presence of an eschar, which had been dismissed as the digital gangrene of a Raynaud attack.

Sporadic cases manifesting as endocarditis, pleural empyema, corneal keratitis or osteomyelitis/septic arthritis have also been reported, although these appear to be infrequent. Infections caused by endogenous human Capnocytophaga species are also uncommon but increasingly reported.

In septicemia due to C canimorsus, in addition to fever and chills, the most common initial symptoms are myalgia and gastrointestinal complaints, similar to our case (11). Occasionally, gastrointestinal bleeding manifestations (eg, hemoptysis, hematuria, melena) may be the presenting symptoms, which may be misleading and delay diagnosis (27). Cutaneous manifestations are common and pleomorphic, ranging from a petechial or purpuric rash at one extreme, to purpura fulminans causing peripheral gangrene often necessitating amputation at the other (11,28-30). Anemia and thrombocytopenia may develop in isolation or as part of DIC, the latter occurring in up to 34% of cases of C canimorsus sepsis (10).

In C canimorsus meningitis, other than a possible bite wound on examination (as in the present case), the clinical picture and cerebrospinal fluid findings are distinguishable from bacterial meningitis caused by typical organisms. There is the suggestion that, compared with typical bacterial meningitides, some cases of C canimorsus meningitis may demonstrate a lesser degree of pleocytosis (<1000 white blood cells/mL) along with a high percentage (≥30%) of lymphocytes (31). These cases may be confused with meningitis due to Listeria monocytogenes or, perhaps, viruses; confusion with the latter may lead to premature cessation of antibiotics, which may be disastrous. An interesting sequela of C canimorsus meningitis appears to be permanent sensorineural hearing loss, which has even been described as a primary complaint (31-33). Whether C canimorsus meningitis causes deafness more frequently than other causes of meningitis remains to be demonstrated. Radiological findings are rarely reported in the literature. Generally, computed tomography scanning of the head in affected patients has been denoted as being unchanged from baseline. In the present case, diffusion-weighted magnetic resonance imaging enabled us to appreciate the gravity and devastating pathogenicity of C canimorsus. To our knowledge, there are no reports of purulent ventriculitis or cerebritis caused by this organism described to date.

C canimorsus can also cause endocarditis. One-third of cases occur in individuals with pre-existing cardiac lesions (34). Given its fastidious nature, C canimorsus may be difficult to isolate as the causative organism, prompting one author to suggest it be added to the list of HACEK (Haemophilus species, Aggregatibacter actinomycetemcomitans, Cardiobacterium hominis, Eikenella corrodens and Kingella kingae) group organisms (35). Although aortic and tricuspid valves have been commonly involved in reported cases (34), there are no distinguishing clinical or echocardiographic features specific to C canimorsus. Similar to other infectious endocarditides, C canimorsus endocarditis may be complicated by paravalvular abscess (36), fistula (34), myocarditis (11) and myocardial infarction (37,38). Surgical intervention was required in up to 47% of cases (34).

Pathogenesis
The pathogenic mechanisms underlying Capnocytophaga infections are not well understood but appear to segregate with the ‘lysozymic fermenter’ group. Infections due to DF-1 and related endogenous Capnocytophaga species are primarily reported in patients following mucosal injury (eg, from mucositis and neutropenia associated with cytoreductive chemotherapy [39-41], periodontitis [42] or chorioamnionitis [43,44]). In such cases, an intact mucosal epithelium appears to be a critical factor in host defense.

Infections due to zoonotic Capnocytophaga appear to occur by a different process. The classic risk factors for severe infection with C canimorsus are hypoplassemia and liver disease/cirrhosis, typically from alcohol use (as in the present case). Hyposplenism may confer susceptibility to C canimorsus because of impaired antibody-mediated opsonophagocytosis; this hypothesis is supported by increased phagocytosis and killing of the bacteria, at least by murine macrophages following opsonization with specific antibody, but not with complement (45). The basis for susceptibility in cirrhotic patients may involve the unique enzyme complex of C canimorsus that enables it to harvest amino sugars of glycan chains from host glycopolypeptides; in particular, this complex targets N-acetylgalactosamine residues (46). In liver disease/cirrhosis, there are alterations in the glycosylation of numerous serum glycoproteins, including liver-derived proteins as well as immunoglobulins. Interestingly, as liver disease progresses, an increase in N-acetylgalactosamine-containing glycopolypeptides is measurable (47). It is attractive to speculate, therefore, that the selective susceptibility to C canimorsus in liver disease may reflect the unique opportunism of this species to feed on exactly those substrates that become more readily available.

Treatment
The fastidious nature of Capnocytophaga species, the lack of validated susceptibility testing methods and the lack of interpretive criteria makes the treatment of C canimorsus infections a challenge. Other infections caused by this organism are often managed with empirical therapy based on the clinical presentation and the likely causative agent. C canimorsus infections may be treated with a combination of an aminoglycoside and an antipseudomonal cephalosporin or carbapenem (48). However, the risk of resistance and the potential for adverse effects of prolonged antimicrobial therapy should be considered.

</tr>
</tbody>
</table>
For the different Capnocytophaga species syndromes, targeted therapy ultimately depends on whether the isolate produces β-lactamase. For isolates that do not, penicillins and ampicillins are appropriate. For those that produce a β-lactamase, therapeutic options include a β-lactam/β-lactamase inhibitor combination, a β-lactamase-resistant β-lactam or a carbapenem. Clindamycin, a respiratory fluoroquinolone or doxycycline may be appropriate alternatives, although reports of clinical efficacy in the literature are scant. Combination therapy may be theoretically advantageous, but again, the absolute benefit has not been investigated.

The duration of antimicrobial therapy for treatment of Capnocytophaga species infections is hampered by the absence of randomized studies. As such, extrapolations from other similar infections provide the basis for clinical management. For C. canimorsus meningitis, the recommended length of treatment varies between 14 and 21 days or longer, as for other Gram-negative meningitis infections (13). For endocarditis, the duration of treatment is at least four to six weeks, with monitoring need for surgical intervention, while at least six to eight weeks may be required for bone/joint involvement.

CONCLUSION

C. canimorsus can cause a variety of syndromes. Hyposplenism and alcoholic liver disease are the main risk factors for severe infection; these conditions should raise suspicion for this organism. Its fastidious nature may delay the isolation and appropriate speciation. Antimicrobial susceptibility testing is not standardized. However, clues to its presence should be sought by thorough review of history and physical examination. With appropriate, duly initiated therapy, C. canimorsus meningitis, a potentially fatal infection, has a relatively favourable prognosis compared with other more common bacterial meningitides.

ACKNOWLEDGEMENTS: The authors thank the Laboratoire de santé publique du Québec for their collaboration in identifying C. canimorsus, the causative pathogen in this case. Dr Popiel was the winner of the Canadian Journal of Infectious Diseases and Medical Microbiology Trainee Review Article Award, presented at the Association of Medical Microbiology and Infectious Canada 2013 Annual Conference, April 4 to 6, Quebec City, Quebec.

DISCLOSURES: Dr Vinh has received speaker honoraria and research support from CSL Behring Canada, as these associations do not have direct or indirect relations to this article.
